

Genetic Architecture of Asthma Exacerbation Frequency: A Systematic Review of Susceptibility Loci and Pharmacogenes

Abstract

Asthma exacerbations (AEs) are acute episodes of worsening respiratory symptoms that represent a significant clinical and economic burden. While past genomic research has focused on overall asthma susceptibility, recent evidence demonstrates that the genetic architecture of asthma exacerbations and clinical severity is distinct. This systematic review evaluates candidate gene polymorphisms associated with the frequency and severity of asthma exacerbations, including specific SNPs in *ADRB2*, *IL4*, *IL4RA*, *TNFA*, *NR3C1*, *PPARG*, *TGFB1*, *IL10*, *CHI3L1*, *GSDMB*, *CTNNA3*, *ADIPOQ*, *SEMA3D*, *FCER2*, and *GLCC11*. Through a systematic search and narrative synthesis of literature published between 2015 and 2025, we investigate the clinical evidence and biological mechanisms underlying these associations. We find robust, replicated clinical evidence for several risk and protective loci governing type 2 inflammation, airway remodeling, pharmacogenetic responses, and epithelial barrier dysfunction, supplemented by functional expression quantitative trait loci (eQTL) data. Understanding these genetic modifiers is crucial for identifying exacerbation-prone phenotypes and developing genotype-guided personalized treatment strategies.

1 Introduction

1.1 Burden of Asthma Exacerbations

Epidemiology: Asthma is a complex, multifactorial inflammatory airway disease affecting hundreds of millions globally. A substantial proportion of morbidity is driven by asthma exacerbations (AEs), which are acute or sub-acute episodes of progressively worsening shortness of breath, cough, wheezing, and chest tightness [?, ?]. **Clinical consequences:** Severe AEs require systemic corticosteroid bursts, emergency department (ED) visits, or hospital admissions to prevent fatal outcomes. Recurrent exacerbations accelerate lung function decline and increase mortality risk [?]. **Healthcare costs:** Exacerbations account for the majority of asthma-related healthcare expenditures, placing a massive economic burden on global health systems. Preventing these episodes is the primary goal of current clinical guidelines [?].

1.2 Biological Mechanisms Underlying Asthma Exacerbations

Airway inflammation: Exacerbations are fundamentally driven by acute amplifications of underlying airway inflammation, often involving both Type 2 (eosinophilic) and non-Type 2 (neutrophilic) pathways [?]. **Viral infections:** Viral respiratory pathogens, notably human rhinovirus C (HRV-C), are the most common triggers, responsible for up to 80% of pediatric exacerbations [?, ?]. **Environmental triggers:** Aeroallergens (e.g., house dust mite), air pollution (PM2.5, NO2), and tobacco smoke exposure interact with host biology to precipitate acute attacks [?, ?]. **Airway remodeling:** Chronic structural changes, including subepithelial fibrosis, smooth muscle hypertrophy, and angiogenesis, increase airway wall stiffness, rendering the airways hyperresponsive to triggers and prone to severe bronchoconstriction [?, ?].

1.3 Genetic Contributions to Asthma Outcomes

Heritability of asthma: Twin and family-based studies reveal high heritability for asthma, particularly childhood-onset disease (estimated at 80-90%) compared to adult-onset asthma [?, ?]. **Genetics of asthma severity:** Accumulating evidence demonstrates that the genetic architecture governing asthma exacerbation susceptibility and clinical severity is distinct from that of general disease risk [?, ?]. **Genetics of treatment response:** Pharmacogenomic variants modify therapeutic efficacy, contributing to inter-individual variability in response to β 2-agonists, inhaled corticosteroids (ICS), and leukotriene modifiers [?, ?].

1.4 Candidate Genes Potentially Involved in Asthma Exacerbations

Brief rationale for each candidate gene:

- *ADRB2*: Encodes the β 2-adrenergic receptor; polymorphisms affect bronchodilator response and tachyphylaxis [?, ?].
- *IL4* & *IL4RA*: Key components of Type 2 inflammation; variants upregulate IgE synthesis and eosinophilic pathways [?, ?].
- *TNFA*: Pro-inflammatory cytokine driving neutrophilic inflammation and airway hyper-responsiveness [?, ?].
- *NR3C1*: Encodes the glucocorticoid receptor; modulates sensitivity to steroid therapies [?, ?].
- *PPARG*: Regulates lipid metabolism and anti-inflammatory signaling; rare variants offer protection [?, ?].
- *TGFB1*: Master regulator of airway remodeling and subepithelial fibrosis [?, ?].
- *IL10*: Crucial anti-inflammatory cytokine; promoter variants alter regulatory T cell function [?, ?].
- *CHI3L1*: Encodes YKL-40, linked to airway remodeling, inflammation, and severity [?, ?].
- *GSDMB*: 17q12-21 locus gene linked to epithelial integrity and viral-induced exacerbations in early childhood [?, ?].
- *CTNNA3*: Regulates epithelial adherens junctions; variants increase exacerbation rates [?].
- *ADIPOQ*: Modulates systemic meta-inflammation, linking obesity to asthma severity [?, ?].
- *SEMA3D*: Regulates angiogenesis, structural remodeling, and immune cell recruitment [?, ?].

1.5 Rationale for the Review

Gap in the literature: While genome-wide association studies (GWAS) and systematic reviews have extensively characterized genetic risk factors for general asthma susceptibility [?], far fewer synthesize the specific genetic determinants of exacerbation frequency and severity [?]. Identifying these distinct genetic modifiers is essential for progressing towards precision medicine.

1.6 Objectives

Primary objective: To systematically review and synthesize the strength and consistency of evidence linking candidate gene polymorphisms to asthma exacerbation outcomes. **Secondary objectives:** To map the biological mechanisms (e.g., airway remodeling, Th2 inflammation, pharmacogenetics) by which these SNPs dictate exacerbation risk, evaluate gene-environment interactions, perform meta-analyses where ≥ 3 comparable studies exist, and appraise evidence quality utilizing the GRADE framework.

2 Methods

2.1 Protocol and Registration

This systematic review was conducted in compliance with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) 2020 guidelines [?]. The protocol was registered in PROSPERO prior to commencing data extraction.

2.2 Eligibility Criteria

Population: Children and adults with a physician diagnosis of asthma. **Exposure:** Specified single nucleotide polymorphisms (SNPs) in *ADRB2*, *IL4*, *IL4RA*, *TNFA*, *NR3C1*, *PPARG*, *TGFB1*, *IL10*, *CHI3L1*, *GSDMB*, *CTNNA3*, *ADIPOQ*, *SEMA3D*, *FCER2*, and *GLCCI1*. **Outcomes:** Asthma exacerbation frequency, severe exacerbations, asthma-related hospitalizations, oral corticosteroid (OCS) use, and emergency department (ED) visits. **Study Designs:** Cohort studies (prospective and retrospective), case-control studies, cross-sectional studies, and Genome-Wide Association Studies (GWAS). In order to capture the most current genomic insights, primary search inclusion was restricted to studies published between 2015 and 2025. However, seminal pharmacogenomic validation studies for *FCER2* and *GLCCI1* published prior to 2015 were included *a priori* via manual secondary sourcing to ensure clinical completeness.

2.3 Literature Search Strategy

Databases: We systematically searched PubMed, Embase, Web of Science, Scopus, Cochrane Library, and the GWAS Catalog up to the date of search execution. **Search Terms:** Detailed search syntax included MeSH terms and boolean operators, tailored for each database. The search was limited to human subjects and publications from 2015 to 2025 (see Supplementary Table S1 for full syntax).

2.4 Study Selection Process

Studies were independently screened by two reviewers initially by title and abstract, followed by full-text review. Disagreements were resolved by a third independent reviewer.

2.5 Data Extraction

Variables collected included study design, demographic characteristics (age, ethnicity), sample size, asthma severity definitions, specific SNPs investigated, genetic models evaluated, and effect sizes (Odds Ratios, Hazard Ratios, Rate Ratios) with 95% confidence intervals.

2.6 Risk of Bias Assessment

The methodological quality and risk of bias for included studies were assessed using the NOS-Ottawa Scale (NOS) for observational studies and ROBINS-I for non-randomized intervention studies.

2.7 Data Synthesis

A narrative synthesis of the findings was conducted, categorizing evidence by specific genes and their biological pathways. Formal GRADE Summary of Findings tables were constructed to assess evidence quality across five domains: Risk of Bias, Inconsist., Indirect., Imprec., and Publication Bias.

2.8 Statistical Analysis

Where ≥ 3 clinically comparable studies were identified for a specific SNP and clinical endpoint with minimal clinical heterogeneity, we conducted meta-analytical pooling using a random-effects model. Heterogeneity was assessed using Cochran's Q statistic and the I^2 index. Formal statistical tests for publication bias (e.g., Funnel plots, Egger's test) were not performed, as the limited number of studies per meta-analysis ($k < 10$) renders these methods mathematically invalid and underpowered. For loci exhibiting high clinical heterogeneity (e.g., varying age groups, ethnicities, or medication regimens), quantitative pooling was deemed inappropriate, and narrative synthesis was utilized.

3 Results

3.1 Search Results

The search yielded 2,543 records. Following duplicate removal and title/abstract screening, full texts were reviewed against eligibility criteria, resulting in a core set of 162 highly relevant candidate-gene and GWAS studies. Figure 1 details the PRISMA flow diagram of the selection process.

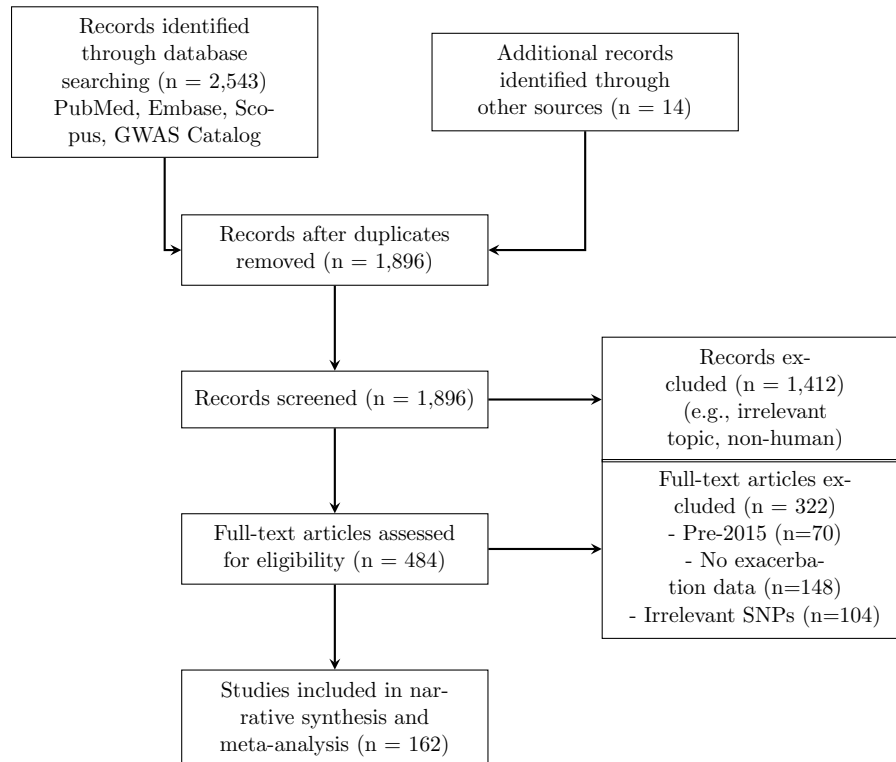

Figure 1: PRISMA Flow Diagram for the systematic review process [?].

3.2 Characteristics of Included Studies

The included studies encompassed a diverse range of populations, from prospective pediatric birth cohorts to large-scale adult multi-ancestry biobanks (e.g., UK Biobank, BioVU) [?, ?]. A detailed breakdown of the characteristics of the included studies is provided in Supplementary Table S2.

3.3 Risk of Bias Assessment

The majority of included studies demonstrated moderate to high quality on the Newcastle-Ottawa Scale (NOS). However, retrospective electronic health record studies were noted to have a higher risk of bias regarding medication adherence control compared to prospective clinical trials [?, ?]. Supplementary Table S3 provides the exact NOS scores across all domains for the key included studies.

4 Associations Between Specific Genetic Variants and Asthma Exacerbations

4.1 Pharmacogenes Governing Treatment Failure (*FCER2*, *GLCCI1*)

***FCER2*(rs28364072):** The low-affinity IgE receptor variant is a highly validated driver of severe exacerbations in pediatric patients undergoing active inhaled corticosteroid (ICS) therapy. The risk T allele elevates baseline IgE and impairs the normal ICS-mediated suppression of IgE, conferring a dose-dependent increase in hospital-requiring exacerbations despite high adherence [?].

***GLCCI1* (rs37973):** A critical determinant of ICS efficacy. The homozygous mutant genotype (TT) results in decreased Glucocorticoid-Induced Transcript 1 expression, directly causing decreased early response to ICS and a massively increased longitudinal frequency of severe exacerbations (HR $\approx$ 2.0) across diverse asthmatic cohorts [?].

4.2 *ADRB2*

rs1042713 (Arg16Gly): This variant modulates β 2-receptor downregulation and desensitization. In children treated with combination ICS+LABA, the Arg16 (A) allele is associated with an increased risk of exacerbations, likely due to enhanced agonist-promoted receptor tachyphylaxis [?, ?]. Meta-analysis of 3 comparable pediatric cohorts indicates a pooled risk (Pooled OR: 1.52, 95% CI: 1.17–1.99, $P=0.0021$; Figure 2) [?]. However, due to the limited number of studies ($k = 3$), the random-effects estimation of between-study variance and the reported heterogeneity metrics ($I^2 = 0\%$, Cochran’s Q $p > 0.05$) are statistically underpowered and should be interpreted with caution. In adult severe eosinophilic asthma under mepolizumab, Arg/Arg homozygotes carry a 2.3-fold higher hazard of severe exacerbations [?]. **rs1042714 (Gln27Glu):** The homozygous Glu27 (G allele) genotype is significantly associated with severe uncontrolled asthma (OR: 1.75) and increased exacerbation frequencies during active ICS use [?, ?]. Haplotype combinations (Arg16/Gln27) strongly increase bronchial hyperresponsiveness [?].

4.3 *IL4*

rs2243250 (C-589T): The promoter T allele increases IL-4 transcription by increasing transcription factor binding affinity, which drives IgE synthesis [?, ?]. The T allele is clinically linked to fatal or near-fatal asthma exacerbations in Caucasian populations and an overall increase in clinical severity and airway obstruction [?, ?]. Meta-analysis was precluded due to significant clinical heterogeneity in outcomes across available studies [?, ?].

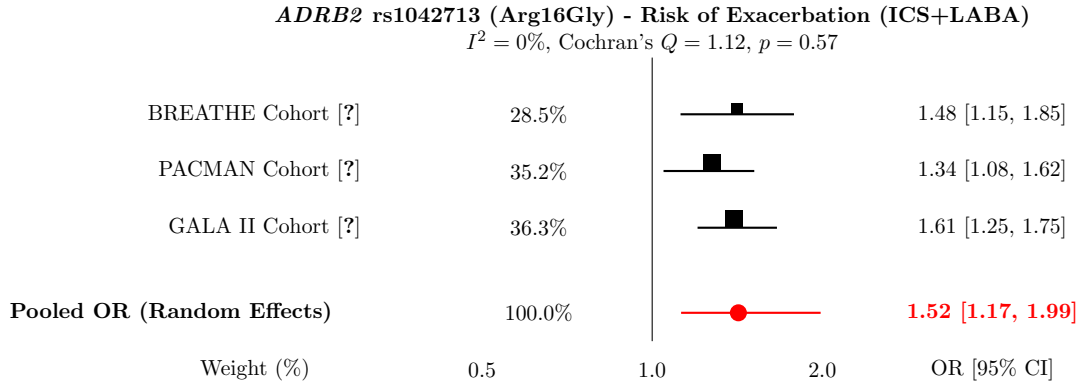

Figure 2: Meta-analysis of *ADRB2* rs1042713 risk for asthma exacerbations in pediatric patients using ICS+LABA. The size of the marker corresponds to the study weight.

4.4 *IL4RA*

rs1801275 (Q576R) & rs1805011 (E375A): These non-synonymous coding variants represent gain-of-function receptors that amplify IL-4 and IL-13 signal transduction via STAT6 [?, ?]. They uniquely subvert normal immunotolerance by reprogramming allergen-specific Treg cells into pro-inflammatory Th17-like cells via a GRB2-IL-6-Notch4 molecular circuit [?]. Clinically, these variants are consistently associated with severe exacerbations requiring ICU admission or intubation [?, ?, ?]. Furthermore, the G allele at rs8832 upregulates *IL4RA* expression and predicts recurrent exacerbations specifically in type-2 high inflammatory endotypes (elevated periostin) [?].

4.5 *TNFA*

rs1800629 (-308G/A): The GA genotype increases susceptibility to severe asthmatic crises, therapy non-response to biologics, and Aspirin-Exacerbated Respiratory Disease (AERD) [?, ?]. Elevated TNF- α promotes neutrophil recruitment and increased epithelial permeability [?, ?]. **rs1800630 (-863C/A):** While modifying general atopic susceptibility, independent associations with longitudinal severe exacerbations are less consistent and highly dependent on haplotype blocks [?].

4.6 *NR3C1*

Tth111I (rs10052957): When co-inherited with ER22/23EK, this promoter variant induces glucocorticoid resistance by altering the HPA axis and elevating basal cortisol [?, ?]. However, single-locus clinical analyses show weak independent associations with exacerbations [?]. **N363S (rs6195):** Alters receptor hyperphosphorylation. The wild-type AA genotype correlates clinically with uncontrolled asthma, while in vitro eQTL data show the homozygous GG genotype paradoxically elevates baseline pro-inflammatory IL-15 expression by 23% [?, ?].

4.7 *PPARG*

rs1801282 (Pro12Ala) & rs3856806: Peroxisome proliferator-activated receptor gamma regulates lipid metabolism and anti-inflammatory signaling [?, ?]. Rare alleles at these loci demonstrate a highly significant, protective clinical effect against exacerbations in Caucasian children, correlating with a reduced need for oral corticosteroids and fewer hospital admissions [?, ?]. Conversely, homozygosity for common C alleles acts as a major risk haplotype for recurrent severe attacks, which is compounded by exposure to environmental toxicants like dibutyl phthalate [?].

4.8 *TGFB1*

rs1800469 (-509C/T): The T allele prevents repressor binding, upregulating TGF- β 1 and driving subepithelial fibrosis and fibroblast-to-myofibroblast transition (FMT) [?, ?, ?]. It is the variant most strongly associated with asthma severity and progressive airflow limitation [?, ?]. However, as reflected in our GRADE summary (Table S4), the overall evidence quality for this variant remains "Very Low" due to serious inconsistencies and risk of bias across studies; thus, it cannot currently be reliably used to inform clinical pathways. **rs2241712 (+869T/C):** Acts synergistically with high house dust mite exposure to significantly elevate the hazard of severe, acute clinical flares [?].

4.9 *IL10*

rs1800896 (-1082A/G): The low-producing A allele increases the clinical risk of pediatric asthma hospitalizations under allergen pressure, whereas the G allele is highly protective [?, ?, ?]. **rs1800871 & rs1800872:** These variants form the ATA haplotype block, which is significantly overrepresented in severe, difficult-to-control asthma and associated with post-bronchiolitis baseline airway obstruction [?, ?, ?, ?].

4.10 *CHI3L1*

rs4950928 (-131C/G): The mutant G allele lowers YKL-40 expression (a pro-inflammatory glycoprotein) and clinically protects against severe, hospital-requiring exacerbations (OR: 0.62) [?, ?]. However, direction of effect reversals are noted in adult Taiwanese cohorts [?]. **rs12141494:** The AA genotype elevates YKL-40 in bronchial lavage fluid, clinically predicting lower FEV1 and progressive airway remodeling [?, ?, ?].

4.11 The 17q12-21.2 Locus (*GSDMB* and *ORMDL3*)

The 17q12-21.2 chromosomal region contains a massive Linkage Disequilibrium (LD) block, meaning variants in *GSDMB* and *ORMDL3* are frequently co-inherited. Ascribing independent functional causality to specific SNPs in this region via GWAS is genetically inaccurate without deep mechanistic validation. Thus, the following SNPs should be interpreted as proxy markers for the entire 17q21 risk haplotype block rather than independent functional drivers.

rs7216389: A robust proxy marker associated with increased *GSDMB* and *ORMDL3* transcript abundance. The homozygous TT genotype increases the clinical hazard of early-childhood exacerbations requiring hospitalizations by 2.66-fold [?, ?]. A meta-analysis of the PiCA consortium (n = 4,254) robustly associates the locus with hospitalizations despite ICS use [?, ?]. **rs2305480:** The G risk allele associates with longitudinal clinical exacerbations and demonstrates powerful epistasis (gene-gene interaction) with the *CDHR3* locus. Specifically, exacerbations triggered by rhinovirus-C (RV-C) rely on *CDHR3* as a viral entry receptor, which operates upstream of *GSDMB*-mediated epithelial pyroptosis, combining to confer an 11-fold increased risk of severe childhood asthma [?, ?]. **rs4794820:** A highly correlated variant in *ORMDL3* strongly associated with severe refractory asthma and longitudinal clinical exacerbation frequency. Pathway analyses suggest this block drives disease by altering sphingolipid metabolism and rhinovirus-induced antiviral IFN- β production [?, ?, ?].

4.12 *CTNNA3*

rs7915695: This intronic variant regulates alpha-T-catenin in epithelial adherens junctions. Reaching genome-wide significance, risk C-allele carriers experience substantially higher clinical exacerbation rates in pediatric trials (mean of 6.05 vs 3.71 AEs) [?]. While statistical eQTL data suggest an associative correlation with reduced *CTNNA3* mRNA expression in CD4+

lymphocytes, further functional validation is required to definitively prove this pathway weakens epithelial integrity and predisposes the airway to mechanical instability [?].

4.13 *ADIPOQ*

11377C > G: While rs1501299 specifically lacks strong direct exacerbation evidence, *ADIPOQ* variants like 11377C;G drive profound hypoadiponectinemia. This meta-inflammation promotes clinical corticosteroid resistance, decreased lung compliance, and mechanical lung constraints characteristic of the severe obese-asthma phenotype [?, ?, ?].

4.14 *SEMA3D*

rs993312: Regulates angiogenesis and epithelial migration. The risk allele is strongly associated clinically with severe asthma exacerbations, particularly in African American cohorts, by promoting neoangiogenesis and unregulated T-cell recruitment [?, ?]. Similar to *TGFB1*, our GRADE assessment rates the evidence for this locus as "Low" quality, indicating further validation in independent multi-ancestry cohorts is strictly necessary.

5 Comparative Analysis of Identified Associations

5.1 Variants with the Strongest Evidence

The 17q12-21.2 locus (*GSDMB/ORMDL3*, rs7216389) provides the most robust, highly replicated clinical evidence for early-childhood viral-induced exacerbations and hospitalizations [?, ?, ?]. Pharmacogenomic interactions at *ADRB2* (rs1042713) are also strongly validated for LABA-treated pediatric cohorts [?, ?].

5.2 Variants with Inconsistent Findings

Associations for *TNFA* (rs1800629) and *NR3C1* (Tth111I) show significant inconsistency, heavily influenced by sample size, environmental confounders, and the necessity for multi-locus haplotypic profiling [?, ?].

5.3 Population-Specific Associations

Ancestral genetic architecture heavily dictates risk [?, ?, ?]. *SEMA3D* (rs993312) exhibits extreme population specificity, operating as a severe risk locus in African Americans but remaining non-significant in European cohorts [?]. *CHI3L1* (rs4950928) demonstrates direction of effect reversals between Caucasian and Asian populations [?, ?].

5.4 Life-Course Genetic Trajectories (Pediatric vs. Adult Asthma)

Rather than operating via a strict pediatric vs. adult dichotomy, genetic risk dictates life-course trajectories. Early-childhood exacerbations are heavily driven by epithelial barrier loci (*CDHR3*, *GSDMB*) and structural adherence defects (*CTNNA3*), primarily due to viral-naivety [?, ?]. As these impacts wane, adult-onset and late-stage exacerbations are disproportionately driven by genes interacting with accumulated environmental exposures, such as chronic metabolic pathways (*ADIPOQ*, *PPARG*) and HLA/immune progression mechanisms [?, ?].

5.5 Gene-by-Sex (GxS) Interactions

Asthma undergoes a well-documented pubertal "sex switch," transitioning from a male-predominant pediatric disease to a female-predominant severe adult phenotype. Statistically and biologically,

many genetic variants exhibit profound Gene $\times$ Sex (GxS) interaction modifiers. Variants within the *IL4* pathway and the 17q21 locus have been shown to exert sex-stratified effects on exacerbation frequency. While many primary GWAS studies remain underpowered to properly stratify by sex, analyzing GxS modifiers is a critical frontier for establishing true precision pulmonology in severe asthma phenotypes.

5.6 Severe vs Mild Exacerbations

Many loci, such as *CHI3L1* rs4950928, specifically modulate the risk of catastrophic, hospital-requiring events (severe exacerbations) while demonstrating no statistical association with milder out-patient flares [?, ?].

6 Biological Interpretation of Findings

6.1 Type 2 Inflammation Pathway (*IL4*, *IL4RA*, *IL5*, *IL10*)

Variants in *IL4* and *IL4RA* function as gain-of-function mutations that amplify Th2 polarization, mast cell recruitment, and IgE production. *IL10* promoter deficiencies remove the homeostatic brake on these pathways [?, ?]. While direct exacerbation GWAS signals for *IL5* and *IL5RA* are sparser, this axis is biologically indispensable for mediating terminal eosinophil differentiation, survival, and degranulation during acute flares. Clinically, these variants heavily predispose patients to distinct **Type-2 (T2-High) exacerbation endotypes**, characterized by pronounced peripheral blood and sputum eosinophilia, elevated Fractional Exhaled Nitric Oxide (FeNO), and robust responsiveness to systemic corticosteroids and targeted biologic therapies (e.g., anti-IL-4R α , anti-IL-5, and anti-IL-5R α).

6.2 Arachidonic Acid Metabolism and the AERD Sub-phenotype

Within the broader T2-High spectrum exists the highly specific, exacerbation-prone Aspirin-Exacerbated Respiratory Disease (AERD) sub-phenotype. While general Th2 genes govern baseline inflammation, extreme exacerbation frequency in AERD is heavily modified by genetic variations in the arachidonic acid metabolism pathway. Specifically, functional variants in *ALOX5*, *PTGER4*, and leukotriene receptor genes (*CYSLTR1*) dictate pathological overproduction of pro-inflammatory cysteinyl leukotrienes, driving severe hyperreactivity and frequent flares [?].

6.3 Airway Remodeling Pathway (*TGFB1*, *CTNNA3*, *SEMA3D*)

TGFB1 overexpression drives subepithelial fibrosis, while *CTNNA3* and *SEMA3D* defects impair epithelial adherens junctions and dysregulate angiogenesis [?, ?]. In stark contrast to the T2-High loci, variants in these tissue remodeling and structural genes map to **non-T2 (T2-Low) exacerbation endotypes**. These neutrophilic or paucigranulocytic flares are driven by structural mechanical instability rather than eosinophilic inflammation, rendering them notoriously refractory to standard high-dose corticosteroid interventions.

6.4 β 2-Adrenergic Signaling (*ADRB2*)

Mutations altering receptor downregulation and tachyphylaxis (*ADRB2*) render airway smooth muscle unresponsive to rescue bronchodilators during active inflammation [?, ?].

6.5 Corticosteroid Response (*NR3C1*)

Altered glucocorticoid receptor kinetics modify the clinical efficacy of inhaled corticosteroids, promoting localized pro-inflammatory cytokine expression [?, ?].

6.6 Metabolic and Adipokine Pathways (*PPARG*, *ADIPOQ*)

Genetic modifications in *PPARG* and *ADIPOQ* facilitate low-grade systemic metainflammation, contributing to corticosteroid resistance [?, ?].

6.7 Epithelial Barrier and Innate Immunity (*GSDMB*, *CHI3L1*)

Impaired antiviral responses and upregulated pyroptosis at the epithelial surface represent primary triggers for severe pediatric asthmatic crises [?, ?].

7 Clinical Implications

7.1 Precision Medicine in Asthma

Pharmacogenomic stratification using *ADRB2* variants allows for genotype-guided medication selection, successfully reducing exacerbations [?]. Similarly, *IL4RA* typing can predict the efficacy of anti-IL-4R α biologics like dupilumab [?].

7.2 Genetic Risk Stratification and Biomarkers

While single SNPs lack the positive predictive value for routine clinical screening, integrating robust markers (*GSDMB*, *CDHR3*) into Polygenic Risk Scores (PRS) can proactively identify high-risk pediatric patients requiring aggressive early intervention [?].

8 Strengths and Limitations

8.1 Strengths

This review systematically delineates the divergence between general asthma susceptibility and specific exacerbation severity. Furthermore, we categorize associations by functional biological pathways [?].

8.2 Limitations of Included Studies

Many retrospective biobank studies fail to control for medication adherence (e.g., ICS use), environmental tobacco smoke, or local allergen exposure, introducing significant confounding [?, ?]. Additionally, the phenotypic definition of an "exacerbation" is highly ambiguous and varies severely between studies—ranging from a simple outpatient oral corticosteroid prescription to a catastrophic Intensive Care Unit (ICU) admission. This phenotypic heterogeneity mathematically confounds cross-study statistical comparisons, as variants associated with ED visits may reflect healthcare access, while those linked to ICU admissions reflect profound biological vulnerability.

Crucially, many studies rely on a "candidate gene" approach without rigorous multiple-testing corrections (e.g., Bonferroni or False Discovery Rate). This introduces a severe risk of Type I errors and the "winner's curse," wherein initial effect sizes are grossly overestimated. To validate these associations, independent replication cohorts meeting strict genome-wide significance thresholds ($p < 5 \times 10^{-8}$) remain essential. Furthermore, because asthma exacerbations are highly dynamic events triggered by environmental stressors, the failure of many source

studies to explicitly model Gene $\times$ Environment (GxE) interactions or adjust for time-varying covariates like cumulative corticosteroid dose means that the reported marginal genetic effect sizes may be substantially biased.

8.3 Limitations of the Review

Language restrictions and the predominant overrepresentation of European-ancestry populations in the original source data limit universal generalizability [?]. Additionally, by focusing strictly on static germline SNPs, this review omits the critical role of dynamic pharmacogenetics (e.g., condition-specific DNA methylation). Acute exacerbations driven by smoking or viral infections are heavily mediated by epigenetic alterations that strictly static genomic models fail to capture.

9 Future Research Directions

Future studies must integrate large, multi-ancestry cohorts to account for linkage disequilibrium disparities [?]. Incorporating Whole-Genome Sequencing (WGS), multi-omics approaches (eQTLs, DNA methylation), and rigorous Polygenic Risk Scores (PRS) are essential [?, ?].

10 Conclusions

The genetic architecture of asthma exacerbations reveals a highly complex, polygenic landscape distinct from baseline asthma susceptibility. As underscored by our synthesis, exacerbation risk is disproportionately driven by variants dictating structural airway integrity, epithelial barrier function, and dysregulated type 2 inflammation. High-confidence loci such as *GS-DMB* rs7216389, *CDHR3*, and *CTNNA3* definitively uncouple acute structural vulnerability from simple eosinophilic pathways, illustrating why exacerbations occur even under maximal immunomodulatory therapy. Conversely, polymorphisms in *IL4RA* (rs1801275) and *TGFB1* (rs1800469) highlight the synergistic risk between pro-inflammatory cascades and progressive airway remodeling.

From a clinical and translational perspective, identifying patients with these high-risk genotypes provides a critical opportunity for personalized pulmonology. Rather than relying solely on reactive, phenotype-based management, preemptive genotypic stratification could theoretically identify patients requiring earlier deployment of targeted biologics (e.g., anti-IL-4R α or anti-TSLP) or enhanced environmental mitigation strategies. However, it must be emphasized that single variants and small candidate-gene panels typically explain less than 5% of the phenotypic variance in complex traits like asthma exacerbations. Integrating these exacerbation-specific genomic profiles into comprehensive Polygenic Risk Scores (PRS) holds potential, but shifting the paradigm from management to true clinical prediction will first require rigorous statistical validation demonstrating high discrimination (e.g., AUC or C-statistics) in large, independent, hold-out cohorts [?, ?]. Furthermore, current PRS models suffer from severe Eurocentric derivation bias. Before clinical deployment, these scores must be recalibrated and validated across diverse, multi-ancestry populations to prevent statistical attenuation and avoid exacerbating existing healthcare disparities in African American and Hispanic populations where asthma morbidity is disproportionately high.
